Old- versus New-Style Header Files

Header File Content Gotchas

New Implementation Gotchas

Why??

How??

Namespaces and "using"

Namespaces and Standard Headers

What does this buy you?

Old- versus New-Style Header Files A14. NewStyle C++ Headers 2

The adoption of the C++ Standard officially brought a number of changes to the language. One of the most visible was the creation of a new set of header files (largely motivated by the adoption of the namespace mechanism).

A C++ programmer is now confronted with two sets of standard header files, related by a naming convention, and with a host of similarities and differences:

Old style:	New style:
iostream.h	iostream
fstream.h	fstream
string.h	string
math.h	cmath
stdlib.h	cstdlib

In general, old-style C++ header files are replaced by new-style headers whose names omit the ".h" suffix. Some headers, such as math.h, were inherited from the C language. In those cases, the new-style headers prefix a "c" to the name and omit the ".h".

In general, the corresponding old- and new-style header files declare more-or-less the same types and serve the same purpose. However, there are a number of important exceptions. A sampling:

iostream.h	iostream
standard stream stuff	same type names, but some subtle differences in implementation
fstream.h	fstream
file stream stuff;	file stream stuff; does
includes iostream.h	NOT include iostream.h
string.h	string
C-style char arrays	string object library

Do not make the mistake of assuming that this is a complete list of the issues.

There are also implementation differences (improvements, **really**!) that can cause problems. For instance:

```
// Example: fstream gotcha
#include <fstream>
using namespace std;
```

```
void printHeader(ofstream Out);
```

```
void main() {
```

```
ofstream oFile("dump.txt");
printHeader(oFile);
oFile.close();
```

```
void printHeader(ofstream Out) {
```

```
Out << "header" << endl;
```

This program will cause a runtime exception, after writing to the output file and after closing the stream.

The reason is a deadly combination:

- Out is passed by value
- no deep copy constructor is provided for the ofstream class

The error does not occur when using the old-style header files. Evidently, this is because there is a deficiency in the old-style destructor for ofstream objects.

Moral: ALWAYS pass stream objects by reference.

4

Why??

Who are we to question the 9-year deliberations of the C++ Standards Committee? Seriously, it doesn't matter. The fact is that we have to deal with the situation as it is. A few observations:

- The new-style headers offer enhanced functionality.
- There are some S/E advantages incorporated into the new-style implementation.
- Therefore, use the new-style approach whenever possible.
- Never, ever, mix old- and new-style headers in the same compilation unit. If possible don't mix them in the same program.

How??

6

A <u>namespace</u> is a scope with a name attached. That is:

```
namespace FooSpace {
                                     A namespace may contain declarations
                                     and/or definitions. The elements of a
   typedef struct {
                                     namespace can only be accessed by using
       string Message;
                                     one of several syntactic structures:
       int
               Target;
   } Foo;
   const int MaxFoo = 1000;
   int numFoo;
                                      cout << FooSpace::numFoo;</pre>
   Foo List[MaxFoo];
                                        . .
};
                                      using FooSpace::numFoo;
                                      cout << numFoo;
                                      cout << List[0].Message;</pre>
 Error. List[] is not declared in
 the present scope.
                                      using namespace FooSpace;
                                      cout << numFoo;</pre>
                                      cout << List[0].Message;</pre>
```

Namespaces and Standard Headers A14. NewStyle C++ Headers

The new-style C++ header files are all wrapped in a single namespace, called std:

```
// foobar
#ifndef FOOBAR
#define FOOBAR
namespace std {
   // declarations
}
#endif
```

Namespaces may be composed; that is, two with the same name are automatically concatenated by the preprocessor.

So it's not enough to #include the right header files; you also must make appropriate use of "using". For now, just apply a using directive as shown before.

What about the old-style headers?

They didn't escape:

```
// foobar.h
#ifndef FOOBAR_H
#define FOOBAR_H
namespace std {
   // declarations
}
using namespace std;
#endif
```

9

Probably not much just yet. However, Stroustrup suggests the following approach:

Ideally, every entity in a program belongs to some recognizable logical unit ("module"). Therefore, every declaration in a nontrivial program should ideally be in some namespace named to indicate its logical role in the program. The exception is main(), which must be global in order for the run-time environment to recognize it as special.

In fact, global scope is itself considered a namespace, with no name (!). An undisciplined programmer can refer to a global identifier by prefixing the scope-resolution operator (::) to it even if there's a local declaration of the same name:

```
int Stupid = 0;
void F( ) {
  int Stupid = 10;
  cout << Stupid; // local
  cout << ::Stupid; // global
}
```

Hint: you could wrap all those tempting globals into a namespace to protect them.
