IN CS, IT CAN BE HARD TO EXPLAIN  
THE DIFFERENCE BETWEEN THE EASY  
AND THE VIRTUALLY IMPOSSIBLE.

In the 60s, Marvin Minsky assigned a couple of undergrads to spend the summer programming a computer to use a camera to identify objects in a scene.

He figured they'd have the problem solved by the end of the summer.

Half a century later, we're still working on it

1. An AVL tree uses rotations to restructure part of the tree following some insertion operations. (This is also true for some deletion operations, but that's not relevant to the questions being asked.)

Suppose that a new value is inserted to an AVL tree, and as a result a single rotation operation is performed. Suppose the insertion added a new node to the right subtree of a node  $N$ , and the subsequent rotation was performed at that node,  $N$ .

- a) [5 points] Is the rotation performed before the new node is added to the tree, or after the new node is added to the tree?

**After... until we've determined how the insertion of the new node affects the balance factors in its ancestor nodes (path back to the root), we don't have enough information to determine whether any rebalancing will be needed. (Technically, we could determine the new balance factors for the ancestor nodes before physically inserting the new leaf, but that would require keeping track of where the new leaf should wind up after any necessary rotations were performed; there's no gain in doing that.)**

- b) [5 points] What relevant fact must have been true about  $N$ 's two subtrees immediately before the new node was inserted?

**The right subtree of  $N$  must have had exactly one more level than the left subtree of  $N$ .**

**We know the insertion caused a rotation due to a bad balance factor at  $N$ , and the insertion was performed in the right subtree of  $N$ ... therefore, the right subtree of  $N$  must have had two more levels (than the left subtree) after the insertion was performed. And, inserting a leaf cannot increase the number of levels in the subtree by more than 1.**

- c) [5 points] Continuing from the situation described in part b), what relevant fact must have been true about  $N$ 's two subtrees immediately after the new node was inserted, but before any rotations were performed?

**The right subtree must have had two exactly more levels than the left subtree.**

**See comments for part b).**

- d) [5 points] Let's suppose that, before the insertion was performed,  $N$  was the left child of its parent node,  $P$ . After the single rotation has been performed, the node  $N$  will have been shifted within the tree, and a different node will now be the left child of  $P$ .

From  $P$ 's perspective, how will the left subtree  $P$  had before the insertion compare to the left subtree it has after the insertion and rotation?

**The key point is the entire reason we perform the rotations: after the insertion and rotation,  $P$ 's left subtree will have exactly the same number of levels as it had before the insertion, so the rotation prevented the subtree from getting taller.**

**Lesser points:**

- **$P$ 's left child after the rotation was the right child of  $N$  before the insertion**
- **$P$ 's left subtree contains one more node than before the insertion**

2. [10 points] In an AVL tree, rebalancing after an insertion never requires more than two single rotations (if we think of a double rotation as a sequence of two single rotations). Since the cost of a single rotation is  $\Theta(1)$ , the cost of rebalancing after an insertion only adds a small constant cost to the insertion (compared to a plain BST).

On the other hand, rebalancing after a deletion may require a single rotation at (essentially) every level, all the way to the root node of the tree. Even so, the cost of a deletion, including all the rebalancing, is still  $\Theta(\log N)$ . Explain why.

The cost of all those single rotations cannot be more than a constant times the number of levels in the AVL tree.

An AVL tree with  $N$  nodes is guaranteed to have  $\Theta(\log N)$  levels.

Therefore, the total cost of the deletion is no worse than the cost of going to the bottom level, plus the cost of the physical deletion of a node plus the cost of backing out and restructuring, which is  $\Theta(\log N + 1 + \log N) = \Theta(\log N)$ .

A complete answer will explain the complexity result entirely.

- 
3. [10 points] How does the worst-case cost of a single insertion to a splay tree compare to the worst-case cost of a single insertion to an AVL tree, if we (fairly) take into account the cost of the rotation operation(s) that would be required in each case? Be precise.

In an AVL tree, after inserting a new node, we never need more than two single rotations to rebalance. Since the number of levels for an AVL tree with  $N$  nodes is  $\Theta(\log N)$ , the cost of the insertion is no worse than  $\Theta(\log N)$ .

For a splay tree with  $N$  nodes, the number of levels is only guaranteed to be  $O(N)$ . However, the splay tree will perform NO rotations after an insertion. So, if the found node is in the lowest level of the tree, the cost of the insertion, which involves NO rebalancing, could be as large as  $\Theta(N)$ .

A common error was to say the splay tree will perform rotations after an insertion (or a deletion).

4. [10 points] Suppose you are building an application that will involve performing a large number of searches on a huge collection of data records, stored in a file on disk. One type of search will involve a key that is a non-negative integer, an ID number. Each record is guaranteed to have a different value for that key. You have decided you will handle these searches by building an index in memory, and the index will use some sort of binary search tree for its physical structure. You have chosen a binary search tree, instead of a hash table, because the application will also involve a substantial number of insertions and deletions.

Research has convinced you that when your application is in use, searches will exhibit high temporal locality, involving a rather small percentage of the data records. What kind of binary search tree should you adopt for your application? Why?

If we expect high temporal locality with respect to a small subset of the data records, then we expect something like the 80/20 Rule to apply to searching.

In that case, we should prefer a splay tree to an AVL tree, since we expect the splay tree will keep the most-searched-for records in the upper levels of the tree, and give us lower average search cost.

The AVL guarantees an excellent  $\Theta(\log N)$  bound on the cost of every search, but it does not take advantage of the presence of temporal locality.

And, of course, we would prefer that to a plain BST, which doesn't even give a good bound on the number of levels.

A complete answer would not only explain why the splay tree would be good, but why the obvious alternative would not be as good.
